Deep generative models

A latent variable model perspective

51st SLAC Summer Institute

Outline

1. Deep generative models
2. Variational auto-encoders
3. Diffusion models
4. Normalizing flows
Deep generative models
Generative models

A (deep) generative model is a probabilistic model $p_{\theta}$ that can be used as a simulator of the data.

Formally, a generative model defines a probability distribution $p_{\theta}(x)$ over the data $x \in \mathcal{X}$, parameterized by $\theta$. 
Variational auto-encoders  
(Kingma and Welling, 2013)

Diffusion models  
(Midjourney, 2023)
Simulators

A simulator prescribes a generative model that can be used to simulate data $\mathbf{x}$. 

- **Collider data**
  - particles $\sim p(\text{particles})$

- **Cosmology data**
  - particles $\sim p(\text{particles})$

- **Molecular dynamics**
  - configurations $\sim p(\text{configurations})$
Conditional simulators

A conditional simulator prescribes a way to sample from the likelihood \( p(x | \theta) \), where \( \theta \) is a set of conditioning variables or parameters.

**Cosmology data**

\[
\text{map} \sim p(\text{map} | \{\Omega_m, \sigma_8, w_0\})
\]

\[
x \sim p(x; \mathcal{M})
\]

or

\[
x \sim p(x | \theta)
\]

[Credit: Siddharth Mishra-Sharma, 2023.

[Credit: Siddharth Mishra-Sharma, 2023.]
\[ p(z_s | \vartheta) = \int p(z_p | \vartheta) p(z_s | z_p) dz_p \]
\[ p(z_d | \vartheta) = \int \int p(z_p | \vartheta) p(z_s | z_p) p(z_d | z_s) dz_p dz_s \]

Latent variables

Detector interactions

Shower splittings

Parton-level momenta

Theory parameters

\( z_d \)

\( z_s \)

\( z_p \)

\( \vartheta \)
\[
p(x|\vartheta) = \iint p(z_p|\vartheta)p(z_s|z_p)p(z_d|z_s)p(x|z_d)dz_pdz_sdx
\]
What can we do with generative models?

- Produce samples
  \[ x \sim p(x|\vartheta) \]

- Evaluate densities
  \[ p(x|\vartheta) \]

- Encode complex priors
  \[ p(\vartheta|x) = \frac{p(x|\vartheta)p(\vartheta)}{p(x)} \]

Variational auto-encoders
Consider for now a **prescribed latent variable model** that relates a set of observable variables \( \mathbf{x} \in \mathcal{X} \) to a set of unobserved variables \( \mathbf{z} \in \mathcal{Z} \).

The probabilistic model defines a joint probability distribution \( p_{\theta}(\mathbf{x}, \mathbf{z}) \), which decomposes as

\[
p_{\theta}(\mathbf{x}, \mathbf{z}) = p_{\theta}(\mathbf{x}|\mathbf{z})p(\mathbf{z}).
\]
How to fit a latent variable model?

\[ \theta^* = \arg \max_{\theta} p_\theta(x) \]

\[ = \arg \max_{\theta} \int p_\theta(x|z)p(z)dz \]

\[ = \arg \max_{\theta} \mathbb{E}_{p(z)} [p_\theta(x|z)] dz \]

\[ \approx \arg \max_{\theta} \frac{1}{N} \sum_{i=1}^{N} p_\theta(x|z_i) \]
How to fit a latent variable model?

\[
\theta^* = \arg \max_{\theta} p_\theta(x)
\]

\[
= \arg \max_{\theta} \int p_\theta(x|z)p(z)dz
\]

\[
= \arg \max_{\theta} \mathbb{E}_{p(z)} [p_\theta(x|z)] dz
\]

\[
\approx \arg \max_{\theta} \frac{1}{N} \sum_{i=1}^{N} p_\theta(x|z_i)
\]

The curse of dimensionality will lead to poor estimates of the expectation.
Variational inference

Let us instead consider a variational approach to fit the model parameters $\theta$.

Using a variational distribution $q_\phi(z)$ over the latent variables $z$, we have

$$
\log p_\theta(x) = \log \mathbb{E}_{p(z)} [p_\theta(x|z)] \\
= \log \mathbb{E}_{q_\phi(z)} \left[ \frac{p_\theta(x|z)p(z)}{q_\phi(z)} \right] \\
\geq \mathbb{E}_{q_\phi(z)} \left[ \log \frac{p_\theta(x|z)p(z)}{q_\phi(z)} \right] \quad \text{(ELBO(x; $\theta$, $\phi$))} \\
= \mathbb{E}_{q_\phi(z)} \left[ \log p_\theta(x|z) \right] - \text{KL}(q_\phi(z)||p(z))
$$
Using the Bayes rule, we can also write

\[
\text{ELBO}(x; \theta, \phi) = \mathbb{E}_{q_\phi(z)} \left[ \log \frac{p_\theta(x|z)p(z)}{q_\phi(z)} \right]
\]

\[
= \mathbb{E}_{q_\phi(z)} \left[ \log \frac{p_\theta(x|z)p(z)}{q_\phi(z)} \frac{p_\theta(x)}{p_\theta(x)} \right]
\]

\[
= \mathbb{E}_{q_\phi(z)} \left[ \log \frac{p_\theta(z|x)}{q_\phi(z)} p_\theta(x) \right]
\]

\[
= \log p_\theta(x) - \text{KL}(q_\phi(z)\|p_\theta(z|x)).
\]

Therefore, \(\log p_\theta(x) = \text{ELBO}(x; \theta, \phi) + \text{KL}(q_\phi(z)\|p_\theta(z|x)).\)
Provided the KL gap remains small, the model parameters can now be optimized by maximizing the ELBO,

\[ \theta^*, \phi^* = \arg \max_{\theta, \phi} \text{ELBO}(x; \theta, \phi). \]
So far we assumed a prescribed probabilistic model motivated by domain knowledge. We will now directly learn a stochastic generating process $p_{\theta}(\mathbf{x}|\mathbf{z})$ with a neural network.

We will also amortize the inference process by learning a second neural network $q_{\phi}(\mathbf{z}|\mathbf{x})$ approximating the posterior, conditionally on the observed data $\mathbf{x}$. 
Variational auto-encoders
As before, we can use variational inference to jointly optimize the generative and the inference networks parameters \( \theta \) and \( \phi \):

\[
\begin{align*}
\theta^*, \phi^* &= \arg \max_{\theta, \phi} \mathbb{E}_{p(x)} [\text{ELBO}(x; \theta, \phi)] \\
&= \arg \max_{\theta, \phi} \mathbb{E}_{p(x)} \left[ \mathbb{E}_{q_{\phi}(z|x)} \left[ \log \frac{p_{\theta}(x|z)p(z)}{q_{\phi}(z|x)} \right] \right] \\
&= \arg \max_{\theta, \phi} \mathbb{E}_{p(x)} \left[ \mathbb{E}_{q_{\phi}(z|x)} \left[ \log p_{\theta}(x|z) \right] - \text{KL}(q_{\phi}(z|x)||p(z)) \right].
\end{align*}
\]
Step-by-step example

Consider as data $d$ the MNIST digit dataset:
Encoder
$q_{\phi}(z|\mathbf{x})$

Decoder
$p_{\theta}(\mathbf{x}|z)$
(a) 2-D latent space  (b) 5-D latent space  (c) 10-D latent space  (d) 20-D latent space

(Kingma and Welling, 2013)
A semantically meaningful latent space

The prior-matching term $\text{KL}(q_\phi(z|x) || p(z))$ enforces simplicity in the latent space, encouraging learned semantic structure and disentanglement.
Diffusion models
Markovian Hierarchical VAEs

\[ p_\theta(x | z_1) \quad p_\theta(z_1 | z_2) \quad p_\theta(z_2 | z_3) \quad p_\theta(z_{T-1} | z_T) \]

\[ q_\phi(z_1 | x) \quad q_\phi(z_2 | z_1) \quad q_\phi(z_3 | z_2) \quad q_\phi(z_T | z_{T-1}) \]
Similarly to VAEs, training is done by maximizing the ELBO, using a variational distribution \( q_\phi(z_{1:T}|x) \) over all levels of latent variables:

\[
\log p_\theta(x) \geq \mathbb{E}_{q_\phi(z_{1:T}|x)} \left[ \log \frac{p(x, z_{1:T})}{q_\phi(z_{1:T}|x)} \right]
\]
Diffusion models

Diffusion models are Markovian HVAEs with the following constraints:

- The latent dimension is the same as the data dimension.
- The encoder is fixed to linear Gaussian transitions $q(x_t | x_{t-1})$.
- The hyper-parameters are set such that $q(x_T | x_0)$ is a standard Gaussian.
With $\epsilon \sim \mathcal{N}(0, I)$, we have

$$x_t = \sqrt{\alpha_t} x_{t-1} + \sqrt{1 - \alpha_t} \epsilon$$

$$q(x_t|x_{t-1}) = \mathcal{N}(x_t; \sqrt{\alpha_t} x_{t-1}, (1 - \alpha_t)I)$$

$$q(x_{1:T}|x_0) = \prod_{t=1}^{T} q(x_t|x_{t-1})$$
Reverse denoising process

\[
p(x_{0:T}) = p(x_T) \prod_{t=1}^{T} p_\theta(x_{t-1}|x_t)
\]
\[
p(x_T) = \mathcal{N}(x_T; 0, I)
\]
\[
p_\theta(x_{t-1}|x_t) = \mathcal{N}(x_{t-1}; \mu_\theta(x_t, t), \sigma_\theta^2(x_t, t)I)
\]
\[
x_{t-1} = \mu_\theta(x_t, t) + \sigma_\theta(x_t, t)z
\]

with \( z \sim \mathcal{N}(0, I) \).
Training

For learning the parameters $\theta$ of the reverse process, we can form a variational lower bound on the log-likelihood of the data as

$$
\mathbb{E}_{q(x_0)} \left[ \log p_\theta(x_0) \right] \geq \mathbb{E}_{q(x_0)q(x_{1:T}|x_0)} \left[ \log \frac{p_\theta(x_{0:T})}{q(x_{1:T}|x_0)} \right] := L
$$
This objective can be rewritten as

\[
L = \mathbb{E}_{q(x_0)} q(x_1:T | x_0) \left[ \log \frac{p_{\theta}(x_{0:T})}{q(x_{1:T} | x_0)} \right] \\
= \mathbb{E}_{q(x_0)} \left[ L_0 - \sum_{t>1} L_{t-1} - L_T \right]
\]

where

- \(L_0 = \mathbb{E}_{q(x_1|x_0)} \left[ \log p_{\theta}(x_0 | x_1) \right]\) can be interpreted as a reconstruction term. It can be approximated and optimized using a Monte Carlo estimate.

- \(L_{t-1} = \mathbb{E}_{q(x_t|x_0)} \text{KL}(q(x_{t-1} | x_t, x_0) || p_{\theta}(x_{t-1} | x_t))\) is a denoising matching term. The transition \(q(x_{t-1} | x_t, x_0)\) provides a learning signal for the reverse process, since it defines how to denoise the noisified input \(x_t\) with access to the original input \(x_0\).

- \(L_T = \text{KL}(q(x_T | x_0) || p_{\theta}(x_T))\) represents how close the distribution of the final noisified input is to the standard Gaussian. It has no trainable parameters.
(Some calculations later...)
\[
\text{arg min}_{\theta} L_{t-1} = \text{arg min}_{\theta} \mathbb{E}_{q(x_t|x_0)} \frac{1}{2\sigma_t^2} \frac{\bar{\alpha}_{t-1} (1 - \alpha_t)^2}{(1 - \bar{\alpha}_t)^2} \| \hat{x}_\theta(x_t, t) - x_0 \|_2^2
\]

*Interpretation 1: Denoising.* Training a diffusion model amounts to learning a neural network that predicts the original ground truth \( x_0 \) from a noisy input \( x_t \).
Interpration 2: Noise prediction. Training a diffusion model amounts to learning a neural network that predicts the noise $\epsilon$ that was added to the original ground truth $x_0$ to obtain the noisy $x_t$. 

$$
\arg\min_{\theta} L_{t-1} = \arg\min_{\theta} \mathbb{E}_{N(\epsilon; 0, I)} \frac{1}{2\sigma_t^2} \frac{(1 - \alpha_t)^2}{(1 - \tilde{\alpha}_t)\alpha_t} \left\| \epsilon_{\theta} \left( \sqrt{\tilde{\alpha}_t} x_0 + \sqrt{1 - \tilde{\alpha}_t} \epsilon, t \right) - \epsilon \right\|^2_2
$$

$$
\approx \arg\min_{\theta} \mathbb{E}_{N(\epsilon; 0, I)} \left\| \epsilon_{\theta} \left( \sqrt{\tilde{\alpha}_t} x_0 + \sqrt{1 - \tilde{\alpha}_t} \epsilon, t \right) - \epsilon \right\|^2_2
$$
Interpretation 3: Denoising score matching. Training a diffusion model amounts to learning a neural network that predicts the score $\nabla_{x_t} \log q(x_t | x_0)$ of the tractable posterior.

\[
\arg \min_\theta L_{t-1} = \arg \min_\theta \mathbb{E}_{q(x_t | x_0)} \frac{1}{2\sigma_t^2} \frac{(1 - \alpha_t)^2}{\alpha_t} \| s_\theta(x_t, t) - \nabla_{x_t} \log q(x_t | x_0) \|^2_2
\]
Network architectures

Diffusion models often use U-Net architectures with ResNet blocks and self-attention layers to represent $\hat{x}_\theta(x_t, t)$, $\epsilon_\theta(x_t, t)$ or $s_\theta(x_t, t)$.

Credit: Kreis et al., 2022.
Continuous-time diffusion models

With $\beta_t = 1 - \alpha_t$, we can rewrite the forward process as

$$x_t = \sqrt{\alpha_t} x_{t-1} + \sqrt{1-\alpha_t} \mathcal{N}(0, I)$$
$$= \sqrt{1 - \beta_t} x_{t-1} + \sqrt{\beta_t} \mathcal{N}(0, I)$$
$$= \sqrt{1 - \beta(t) \Delta_t} x_{t-1} + \sqrt{\beta(t) \Delta_t} \mathcal{N}(0, I)$$

Credits: Kreis et al, 2022.
When $\Delta_t \to 0$, we can further rewrite the forward process as
\[
x_t = \sqrt{1 - \beta(t)\Delta_t} x_{t-1} + \sqrt{\beta(t)\Delta_t} N(0, I)
\approx x_{t-1} - \frac{\beta(t)\Delta_t}{2} x_{t-1} + \sqrt{\beta(t)\Delta_t} N(0, I).
\]

This last update rule corresponds to the Euler-Maruyama discretization of the stochastic differential equation (SDE)
\[
dx_t = -\frac{1}{2} \beta(t)x_t dt + \sqrt{\beta(t)} d\mathbf{w}_t
\]
describing the diffusion in the infinitesimal limit.
The reverse process satisfies a reverse-time SDE that can be derived analytically from the forward-time SDE and the score of the marginal distribution \( q(x_t) \), as

\[
dx_t = \left[ -\frac{1}{2} \beta(t) x_t - \beta(t) \nabla_{x_t} \log q(x_t) \right] dt + \sqrt{\beta(t)} dw_t.
\]
Normalizing flows
Change of variables

Assume $p(z)$ is a uniformly distributed unit cube in $\mathbb{R}^3$ and $x = f(z) = 2z$. Since the total probability mass must be conserved,

\[
p(x = f(z)) = p(z) \frac{V_z}{V_x} = p(z) \frac{1}{8},
\]

where $\frac{1}{8} = \left| \det \begin{pmatrix} 2 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 2 \end{pmatrix} \right|^{-1}$ represents the inverse determinant of the linear transformation $f$. 
What if \( f \) is non-linear?

**Figure 16.2** Transforming distributions. The base density (cyan, bottom) passes through a function (blue curve, top right) to create the model density (orange, left). Consider dividing the base density into equal intervals (gray vertical lines). The probability mass between adjacent lines must remain the same after transformation. The cyan-shaded region passes through a part of the function where the gradient is larger than one, so this region is stretched. Consequently, the height of the orange-shaded region must be lower so that it retains the same area as the cyan-shaded region. In other places (e.g., \( z = -2 \)), the gradient is less than one, and the model density increases relative to the base density.
Change of variables theorem

If $f$ is non-linear,

- the Jacobian $J_f(z)$ of $x = f(z)$ represents the infinitesimal linear transformation in the neighborhood of $z$;
- if the function is a bijective map, then the mass must be conserved locally.

Therefore, the local change of density yields

$$p(x = f(z)) = p(z) |\det J_f(z)|^{-1}.$$  

Similarly, for $g = f^{-1}$, we have

$$p(x) = p(z = g(x)) |\det J_g(x)|.$$
Example: coupling layers

Assume $\mathbf{z} = (\mathbf{z}_a, \mathbf{z}_b)$ and $\mathbf{x} = (\mathbf{x}_a, \mathbf{x}_b)$. Then,

- **Forward mapping** $\mathbf{x} = f(\mathbf{z})$:
  \[
  \mathbf{x}_a = \mathbf{z}_a, \quad \mathbf{x}_b = \mathbf{z}_b \odot \exp(s(\mathbf{z}_a)) + t(\mathbf{z}_a),
  \]

- **Inverse mapping** $\mathbf{z} = g(\mathbf{x})$:
  \[
  \mathbf{z}_a = \mathbf{x}_a, \quad \mathbf{z}_b = (\mathbf{x}_b - t(\mathbf{x}_a)) \odot \exp(-s(\mathbf{x}_a)),
  \]

where $s$ and $t$ are arbitrary neural networks.
For \( \mathbf{x} = (\mathbf{x}_a, \mathbf{x}_b) \), the log-likelihood is

\[
\log p(\mathbf{x}) = \log p(\mathbf{z}) \left| \det J_f(\mathbf{z}) \right|^{-1}
\]

where the Jacobian \( J_f(\mathbf{z}) = \frac{\partial \mathbf{x}}{\partial \mathbf{z}} \) is a lower triangular matrix

\[
\begin{pmatrix}
I \\
\frac{\partial x_b}{\partial z_a} & \text{diag}(\exp(s(\mathbf{z}_a)))
\end{pmatrix},
\]

such that \( \left| \det J_f(\mathbf{z}) \right| = \prod_i \exp(s(\mathbf{z}_a)_i) = \exp(\sum_i s(\mathbf{z}_a)_i) \).

Therefore, the log-likelihood is

\[
\log p(\mathbf{x}) = \log p(\mathbf{z}) - \sum_i s(\mathbf{z}_a)_i
\]
Normalizing flows

A normalizing flow is a change of variable $f$ that transforms a base distribution $p(z)$ into $p(x)$ through a discrete sequence of invertible transformations.

$z_0 \sim p_0(z_0)$

$z_1 = f_1(z_0)$

$z_2 = f_2(z_1)$

$\ldots$

$z_K = f_K(z_{K-1}) = x$

$z_i \sim p_i(z_i)$

Formally,

\[ z_0 \sim p(z) \]
\[ z_k = f_k(z_{k-1}), \quad k = 1, \ldots, K \]
\[ x = z_K = f_K \circ \cdots \circ f_1(z_0). \]

The change of variable theorem yields

\[ \log p(x) = \log p(z_0) - \sum_{k=1}^{K} \log |\det J_{f_k}(z_{k-1})|. \]
Normalizing flows can fit complex multimodal discontinuous densities.
Continuous-time normalizing flows

Replace the discrete sequence of transformations with a neural ODE with reversible dynamics such that

\[
\begin{align*}
\mathbf{z}_0 & \sim p(\mathbf{z}) \\
\frac{d\mathbf{z}(t)}{dt} & = f(\mathbf{z}(t), t, \theta) \\
\mathbf{x} = \mathbf{z}(1) & = \mathbf{z}_0 + \int_0^1 f(\mathbf{z}(t), t) dt.
\end{align*}
\]

The instantaneous change of variable yields

\[
\log p(\mathbf{x}) = \log p(\mathbf{z}(0)) - \int_0^1 \text{Tr} \left( \frac{\partial f(\mathbf{z}(t), t, \theta)}{\partial \mathbf{z}(t)} \right) dt.
\]
**Probability flow ODE**

*Back to diffusion:* For any diffusion process, there exists a corresponding deterministic process

\[
\frac{dx_t}{dt} = \left[ f(t, x_t) - \frac{1}{2} g^2(t) \nabla_{x_t} \log p(x_t) \right] dt
\]

whose trajectories share the same marginal densities \( p(x_t) \).

Therefore, when \( \nabla_{x_t} \log p(x_t) \) is replaced by its approximation \( s_\theta(x_t, t) \), the probability flow ODE becomes a special case of a neural ODE. In particular, it is an example of continuous-time normalizing flows!
The end.
